

# The Effects of Labor Market Opportunities on Education: The Case of a Female Hiring Ceiling in Iran\*

Safoura Moeeni              Atsuko Tanaka

July 23, 2019

## Abstract

This paper estimates the effects of labor market opportunities on educational attainment. We exploit discontinuity generated by a 2010 policy in Iran that limited female employment in the public sector. We find that this hiring quota, which significantly worsened female labor market conditions, immediately reduced women's enrollment in university programs. We also find that those who did not enroll in college after the quota are less likely to be employed, but are more likely to get married young and have a child. Our finding highlights the importance of labor market opportunities for women's education and their work and family decisions.

# 1 Introduction

Over the past half century, women’s educational attainment has substantially increased worldwide. At the same time, more and more women are involved in the paid labor market ([Olivetti and Petrongolo \(2017\)](#)). Even in the Middle Eastern and North African countries, whose educational and gender employment gap has historically been the largest, the female-to-male ratio of average years of schooling increased from 0.63 in 1990 to 0.87 in 2010 (Source: [Barro and Lee \(2013\)](#)). The female-to-male ratio of labor force participation rate in this region also increased from 0.23 in 1990 to 0.30 in 2010 (Source: World Bank). Identifying the driving forces behind gender equality in education and employment is critical for policy makers who want to promote women’s empowerment, which is targeted as one of the most important development elements to alleviate world poverty (The Millennium Development Goals, United Nations). It is also important for economists to understand how people interactively make decisions regarding education and labor force participation in order to assess the impact of a policy such as affirmative action on the targeted outcomes.

This paper looks at changes in labor market opportunities brought about by a discriminatory policy and analyzes how these changes affect people’s education choices with a focus on female workers. Specifically, we answer a general research question: how does limiting labor market opportunities affect education outcomes? Theoretical predictions are ambiguous about the effects of the quota ([Holzer and Neumark \(2000\)](#)). On the one hand, the limited labor market opportunities for educated women could decrease their educational attainment by reducing expected earnings from additional schooling. On the other hand, poor labor market opportunities could increase educational attainment by reducing opportunity costs of schooling. Since the effect could go either way, we conduct formal empirical analysis to answer this question. However, many of the existing papers have difficulty separating the effects of labor demand from other effects. In fact, isolating the impact of labor market opportunity is challenging because various confounding factors simultaneously affect labor market conditions and education outcomes.

To address endogeneity problems, we exploit the quasi-experimental design provided by the Iranian quota that set a ceiling on female employment in the public sector. The case of the Iranian hiring ceiling provides a good experimental environment because the quota was implemented suddenly and only enforced in the public sector. Since the public sector accounts for 17-23% of total employment in Iran, the quota is more likely to have a great effect on expectations toward labor market returns in general. With these sudden changes in labor market opportunities, estimating the effects on education from this data brings new perspectives and complements findings in the existing literature.

The main identification strategy exploits a discontinuity in perceived labor market

opportunities across education cohorts by estimating the Regression Discontinuity models. We define the control cohorts as those who were just over the typical graduation age at each schooling level when the quota was imposed. Our main focus is the effects on high school and college education attainment because we have a clear-cut control group with respect to the outcome of school attendance; as in most developed countries, Iranian students usually follow the entry age cutoff rule set by the government and very few return to school as adults. We first look at the effects on education outcomes; we then keep track of the same cohort whose education decisions are affected by the quota and examine the long-run effects on their later lifetime outcomes such as labor market, marriage, and fertility outcomes. To complement the RDD analysis, we also apply the differences-in-differences method by exploiting how tightly the quota binds across provinces. The cross-provincial variation allows us to estimate the immediate effects on outcomes, including employment in the public/private sector. In doing so, we evaluate the overall effect of reduced labor market opportunity.

Using data comprised of 2,631,000 individuals from 2006 to 2015, we find that the employment ceiling negatively affected women's college attendance and positively affected that of men. The analysis finds that the quota immediately reduced women's enrollment rate in university by 3.0-3.2 percentage points from 41.4%. The quota also increased men's enrollment rate in university by 2.0 percentage points from 42.5%. The reduction in women's enrollment in university programs in turn led to an increase in the marriage rates of women aged 18-24 by 2.4-4.0 percentage points from 11.8%. The quota was enforced as written in the official document; it decreased women's employment and increased men's employment in the public sector. Since the public sector, on average, pays more than the private sector and often requires a college degree, this hiring quota reduced labor market opportunities for educated women and indirectly increased opportunities for educated men. We find no significant effects on employment outcomes for high school graduates or in the private sector. Consequentially, we find no effects on enrollment rates in highschool for either gender. We also find the hiring ceiling decreased the proportion of female students in college majors with strong ties with public employment, and it increased in college majors with weaker associations to the public sector. These findings indicate that the imposition of the hiring ceiling reduced labor market opportunities for educated women and consequentially decreased college enrollment.

Utilizing the age-based (or birth cohort-based) discontinuities is widely adopted applications of a valid RDD design in the other contexts, as discussed in [Lee and Lemieux \(2010\)](#). Some exploit age at school entry variation to study the effects of education on various outcomes. For example, [Cascio and Lewis \(2006\)](#) look at test scores as outcomes of interest; [Oreopoulos \(2006\)](#) and [Dobkin and Ferreira \(2010\)](#) look at earnings. Others

use age-triggered treatments of social insurance eligibility to estimate the effects of social security program reforms on healthcare utilization and health-related outcomes. [Card and Shore-Sheppard \(2004\)](#) use age-triggered treatments of social insurance eligibility to analyze the effects of a Medicaid expansion. More recent studies estimate the effect of the insurance coverage ([Card et al. \(2008; 2009\)](#); [Anderson et al. \(2012\)](#)) and the effect of patient cost-sharing ([Shigeoka \(2014\)](#); [Fukushima et al. \(2016\)](#)) on healthcare utilization. We also exploit the age discontinuity, but look at the effects of labor market opportunities on education attainment.

This paper contributes to the literature by providing evidence on the importance of labor market opportunities as the determinant of women's higher education pursuit. Theoretical and empirical findings show that education has also benefits beyond the labor market. For example, education makes individuals more attractive to potential partners in the marriage market ([Goldin \(1992\)](#); [Lafontaine \(2013\)](#)). Additional education is also thought to increase knowledge on health ([Wagstaff \(1993\)](#); [Kenkel \(1991\)](#)) and prepare individuals for better parenting ([Cunha and Heckman \(2009\)](#)).

While there is a rich body of empirical literature examining the importance of education on labor market outcomes, the causal effects of labor market opportunities on education decisions have been relatively less explored. In fact, there are many influential papers that study education and labor market opportunities ([Mincer \(1962\)](#); [Gronau \(1974\)](#); [Heckman \(1974\)](#); [Heckman and Killingsworth \(1986\)](#); [Neal and Johnson \(1996\)](#), and [Greenwood et al. \(2005\)](#)), but these papers do not focus on the causal relationship between labor market opportunities and education. In fact, exploiting an exogenous variation in labor market opportunities is key for valid identification, yet it is challenging using non-experimental data.

Indeed, many papers look at temporary labor demand changes caused by business cycles and examine how economic booms and recessions affect education (e.g. [Betts and McFarland \(1995\)](#); [Oyer \(2006\)](#); [Kahn \(2010\)](#); [Oreopoulos et al. \(2012\)](#)). However, bad/good economies alter perceived labor market opportunities only temporarily since people anticipate economic recovery sooner or later. In contrast, the employment ceiling in Iran reduced long-term returns to education, creating long-lasting anticipation toward poor labor market opportunities for women. In fact, the direction of reduced labor market opportunities estimated in this paper is opposite to the ones in the literature on business cycles; this paper finds that education attainment decreases when labor market opportunities are reduced while the literature on business cycles finds that education attainment increases during recession.

There are papers that study the effects of long-lasting labor demand changes in the local labor market, but their focus has not been education outcomes but other outcomes such as employment and economic development. Examples of a labor demand shock

are plant construction/closings ([Carrington \(1996\)](#); [Greenstone and Moretti \(2003\)](#)) and military base closings ([Dardia et al. \(1996\)](#); [Hooker and Knetter \(1997; 2001\)](#)). These papers look at changes in employment outcomes. In addition to employment outcomes, [Black et al. \(2003; 2005b\)](#) look at the effect of a local labor demand shock on wages and government expenditure by studying a local labor demand shock induced by the coal boom and bust. There are also many papers interested in outcomes related to economic development. For example, [Erickson and Syms \(1986\)](#) and [Papke \(1994\)](#) study local labor demand changes that took place when the government introduced enterprise zones, considering employment and housing market outcomes with a focus on the spillover effects from labor market shocks in one sector on other sectors. Unlike these papers, our focus is education outcomes.

Among a few studies that estimate the causal effects of long-lasting labor demand shock on education are [Black et al. \(2005a\)](#) and [Jensen \(2012\)](#). [Black et al. \(2005a\)](#) study the effects of a local labor demand shock induced by the coal boom and bust. They look at men's education, but not women's education because the labor demand shocks have most commonly affected male-dominated industries. [Jensen \(2012\)](#) conducted a randomized trial that increased perceived labor market opportunities for young women in rural Indian villages by actively advertising job positions. Unlike these papers, the source of the labor demand shock studied in this paper affects women economy-wide. By exploiting a greater gap in labor market opportunities, our analysis complements findings in the literature well.

This paper also complements literature that studies the hiring quota: the system is commonly used as an affirmative action policy for a disadvantaged group. Indeed, the role of the quota that sets a hiring floor is empirically tested (e.g. [Holzer and Neumark \(2000\)](#); [McCrary \(2007\)](#); [Peck \(2017\)](#)). However, a quota that sets a hiring ceiling for a disadvantaged group is very rare. Due to the scarce incidence of hiring ceilings like this and, correspondingly, the limited resulting data, few studies have examined the effect of a hiring ceiling on a disadvantaged group. We find that the hiring ceiling substantially decreased women's education, showing symmetric effects of positive and negative shocks to labor market opportunities on education decisions.

## 2 Background

### 2.1 Labor Market

The labor market and education in Iran are similar to those in middle/high income Middle East and North African (MENA) countries. In 2008-2009, the years before the quota was instituted, the Iranian female labor force participation rate was 15.4-

16.2%. Women accounted for 18.43-18.49% of the Iranian labor force. The public sector provided a non-trivial portion of job openings to both men and women when the quota was instituted: of those employed, 17.2% of male workers and 22.7% of female workers engaged in public sector jobs in 2008, respectively, and the rest work in the private sector (Source: World Bank; Statistical Center of Iran).

Most jobs in the public sector require college degrees. In fact, 82% of workers in the public sector have a post-secondary degree. Workers in the public sector are experts, office workers, and technicians and often classified as high-skilled workers. While only 6% of employees in the private sector are classified as experts, 64% of employees in the public sector were experts in 2008. This trend continues in 2014: 12% of employees in the private sector were experts, compared to 66% in the public sector (Source: Statistical Center of Iran). The jobs in the public sector are mostly white-collar jobs and are relatively well paid. The starting salary in the public sector is as double as the one in the private sector. As of 2016, the ranges for starting monthly salaries of the public sector jobs with no experience ranges start from 1,500,000 Iranian rial, which roughly corresponds to 450 USD (The exchange ratio used here: 1 Iranian rial = 0.00003 US Dollar as of January, 2016). The salaries of private sector jobs start from approximately 800,000 Iranian rial (approximately 200 USD). The public sector rarely fires workers and thus provides more job security. According to Iranian labor law, termination of the employment contract is allowed only under the following instances: 1. Death of employee; 2. Retirement of employee; 3. Total disability of employee; 4. Expiration of the duration of the employment contract; 5. Conclusion of work in task specific contracts; and 6. Resignation of the employee. Given that the public sector, on average, pays more than the private sector and often requires a college degree, the hiring quota is expected to have reduced labor market opportunities for educated women and indirectly increased opportunities for educated men.

## 2.2 Education

Although Iran is culturally similar to other MENA countries such as Turkey and Egypt, women's educational advancement in Iran resembles Western countries in some aspects rather than other MENA countries; for example, college education is heavily subsidized and credit constraints are of less importance in Iran. In Iran, compulsory primary education, high school education, and public higher education are all tuition free. Compared to other MENA countries, women's education attainment in Iran is very high. While there is a large gender gap in terms of labor force participation, women's educational attainment is similar to that of men in Iran. The school enrollment ratio of girls to boys aged 6 to 15 in 2009 was 98 (Source: World Bank), comparable to that of Western countries. The college enrollment rate of women is also as high as that of men. In 2009,

37.3% of women aged 15-25 with a high school degree attended four-year universities while 34.3% of the corresponding men did so (Source: ILFS data, Statistical Center of Iran). Part of this parity in educational attainment can be explained by the educational subsidy provided by the government.

Given a high education attainment rate for both genders, people are relatively well aware of the market return to education; that is, most Iranian cities do not suffer from the information problem, as do rural communities or small towns where no/few adults have education and people have little information about the potential returns to education. As such, our paper analyzes an environment where there is little barrier to education regarding credit constraints and/or an information problem. While we cannot generalize our findings unconditionally, we think that our analysis is useful in understanding other countries that have similar educational setups.

The Iranian educational system provides exogenous differences across birth cohort, which allows us to apply a sharp RDD method. We use the education cohort as the running variable and, for our method to be valid, we assume individuals cannot self-select themselves into a control or treated cohort in order to avoid/receive treatment. This assumption is plausible in our setup. In Iran, one must be six years old on the starting date of the academic year in order to enter an elementary school.<sup>1</sup> Since grade skipping or returning to school as an adult student is rare, most students enter high schools at age 15 and enter universities at age 18 in Iran.<sup>2</sup> In addition, there are age restrictions for enrollment at each grade. For example, the maximum age eligible for high school education is 20. While there is no age limitation for attending college, in the data, only 5% of college students are aged over 25.<sup>3</sup> By exploiting this age cutoff rule, we use the cohorts that are a few years apart as treated and control groups. The details will be discussed in the empirical section.

### 2.3 The 2010 Female hiring quota

The 2010 Iranian hiring quota, referred to as the quota hereafter, is based on Article 230 of the Fifth Development Plan (2010-2014), a five-year scheme that the Iranian government implemented. According to Article 230, the government declares that they will prepare and approve the “Comprehensive Program for Women and Family Development,” claiming that men should be the breadwinners in a family (For details, see the Appendix A).<sup>4</sup> According to the official record, the quota was only effective in the pub-

<sup>1</sup>The cutoff is based on the age as of September 23rd in the year (Source: The Iranian Ministry of Education).

<sup>2</sup>Source: The Iranian Ministry of Education

<sup>3</sup>Source: The website of the Ministry of Education <http://www.medu.ir/fa/regulations/category/1?ocode=100010876>

<sup>4</sup>Even for female-headed households and women with an unqualified male breadwinner, this program suggests that women should engage in home-based jobs.

lic sector, partly because the government does not have direct control over the private sector.

The hiring quota was announced in early March 2010 and immediately went into effect on March 21st of that year, New Year's Day in the Iranian calendar. This quota set the maximum size of female new hires, and thus tightened the labor market for female workers seeking a job in the public sector. That is, the imposition of the quota resulted in fewer job openings in the public sector for women and more openings for men. As of 2019, the hiring quota is still in effect. While there are changes in policies and economic conditions in Iran, no policy related to education or the labor market is implemented other than the hiring quota in 2010. The potential effects of other policies are discussed in the empirical section when we report robustness check analysis.

The major reason why the Iranian government imposed a female hiring ceiling was to create employment opportunities for men. The government wanted to suppress the surging unemployment rates among men by allocating new job openings to male workers. The government has been especially concerned about men's unemployment rates, which were increasing at a worrying rate and reached a historical high of 10.8% in 2009 (Source: Statistical Center of Iran).<sup>5</sup> Another reason for the hiring ceiling is that the Iranian government thought limiting employment opportunities for women would increase fertility rates. The birth rate in Iran decreased from 6.5 in 1975–1980 to 1.9 in 2005–2010 (Source: The UN's Population Division of the Department of Economic and Social Affairs). A further drop in fertility rates, resulting in an aging population, would be costly from the perspective of public finances. Thus, the government called for a reversal of Iran's population control policy. The hiring quota for female workers is considered a part of the government's attempts to increase the birthrate by reducing alternative options for women (i.e. employment).

The quota is binding for all except one province; in 29 out of 30 provinces, the post-treatment share of women is smaller than pre-treatment share of women (See Table B.1 in the Appendix, which reports how the quota affected each province). While most provinces were affected by the quota, some were more affected than the others. The variations in the quota intensity arise from differences in the concentration of gender-segregated workplaces across geographic location. The quota is set at around 10% with little variation in all occupations in the public sector except gender-segregated workplaces such as hospitals and schools. According to the official documents, regardless of province, the government applied the same quota policy to each occupation group in the public sector. Exempted from the quota policy are the gender-segregated workplaces. Since these gender-segregated workplaces need female public officers to serve for women,

---

<sup>5</sup>In Iran, dominant political parties mainly compete for men's vote since women's vote is often diversified into relatively small parties that seek freedom and democracy.

they continued to allocate a certain proportion of job openings to women even after the quota was imposed. The workplaces that commonly practice gender segregation are hospitals and schools. Since the scale of treatment is large, we will study spillover effects to the private sector as well as effects on men's employment and education outcomes.

## 3 Data and Descriptive Evidence

### 3.1 Data

The main data used in the analysis is from the 2006-2015 Iranian Labor Force Survey (ILFS), a rich and large data set provided by the Statistical Centre of Iran. The data are repeated cross sections that have been collected on the same reference population under rotating panel design. The ILFS collects the data on 140,000-170,000 individuals quarterly using random sampling; it is designed to be representative of the population of Iran.<sup>6</sup> The total number of observations used for the main RDD analysis is 523,220 year-individual observations and 941,811 for the DID analysis. The ILFS data offer detailed information about the respondents' demographic characteristics, birth year and month, employment status, residential area, recent migration, and other important characteristics. We observe whether an individual is enrolled in school and the highest degree of education she/he has ever attained. For those who attend college during the survey period, we observe their college major. The response rates in all rounds are at 81-89%. We also use Iranian Households Income and Expenditure data (2006-2015; IHIE) for analyzing the effects on wages because ILFS data do not contain the information on wages. We have 245,927 year-individual observations in the IHIE data used for the analysis on wage. We do not use the IHIE data for the rest of the analysis because of its small sample size; the IHIS contains fewer than a half of the observations in ILFS data.

In addition to the birth cohort cutoff, we also explore the differences in the intensity of the quota across province in applying the DID method. To measure the intensity of the quota, we use the data provided from Iran's Department for Women and Family Affairs of the Iranian government. We extract the data from a list of PDF files that specifies the number of job openings in each occupation and province in the public sector in 2015. The data provide the information on how many vacant seats are open to men only (80.1% of the total seats), both genders (6.0%), and women only (13.9%).

---

<sup>6</sup>First, the government survey agency divided the whole country into a block containing at least 250 households based on the Census. Second, they selected 85 households in each block, which is called a cluster. Then they divided each cluster into rotation groups for interviewing. That is, a part of the sample is partially replaced while the remainder is retained (i.e., partial replacement). Each rotation group consists of three households in the same neighborhood. We checked the data validity by comparing the data features of the ILFS to those from census and other aggregate data provided by the Iranian government.

We combine the openings to both genders and women and use it as the proportion of female new hires. Since some of the job vacancies open to both genders will be taken by men, the actual proportion of the female new hires is smaller than the estimates. The variance in the proportion of the female new hires is considerable.

### 3.2 Sample

The main sample consists of men and women collected from the 2006-2015 ILFS data. For the RDD analysis, we use individuals' month of birth as the running variable and our sample comprises those who were born just before and after the cutoff points. For the main RDD analysis, we use individuals who are born between 1991 and 1995 for high school attendance and those born between 1986-1990 for college attendance. For the DID, we use those who were born between 1986 and 1995. Note that when we conduct the RDD analysis, we cannot compare the outcomes for the older age cohorts because the treated defined in the RDD analysis are still young in the currently available data set; the oldest is 29 years old in the most recent year in the data.

Table 1: Summary Statistics

| <i>Individual-level variables</i>         | Aug. 1988 and older | Sep. 1988 and younger |
|---|---------------------|-----------------------|
| Number of observations (female)           | 156,648             | 135,090               |
| Number of observations (male)             | 124,714             | 106,768               |
| Age (female)                              | 23.57               | 22.80                 |
| Age (male)                                | 23.55               | 23.06                 |
| % Married women (Age 25)                  | 51.33               | 58.52                 |
| % Women have given birth (Age 25)         | 46.17               | 54.08                 |
| % Married men (Age 25)                    | 30.41               | 28.16                 |
| % Men whose wife has had a child (Age 25) | 13.65               | 17.56                 |
| % Women who work for pay (Age 25)         | 14.85               | 10.89                 |
| % In university: girls (HSG age:18-22)    | 42.80               | 40.63                 |
| % In university: boys (HSG age:18-22)     | 46.87               | 52.32                 |
|   | Aug. 1993 and older | Sep. 1993 and younger |
| % In school: girls (age:15-18)            | 84.34               | 84.03                 |
| % In school: boys (age:15-18)             | 81.19               | 84.83                 |

Notes: The sample for this analysis is all individuals in the working-age who were born just before and after the cutoff points (1991-1995 for high school enrollment, and 1986-1990 for other outcome variables including college enrollment, marriage, and fertility) ( $15 \leq \text{age} \leq 29$ ).

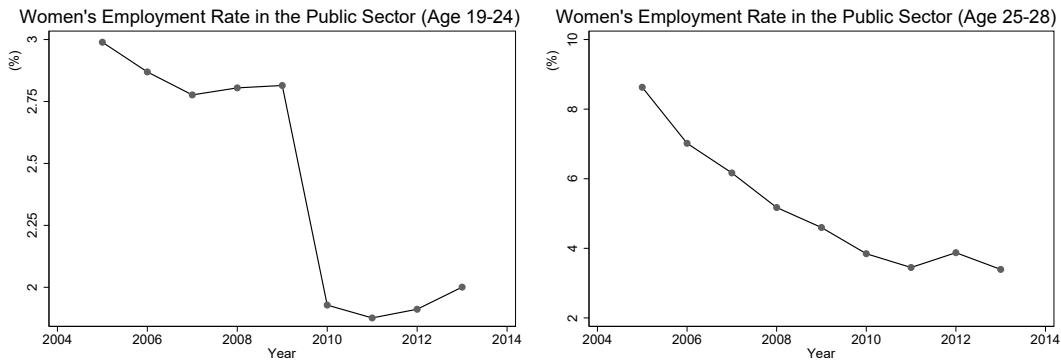

Table 1 presents summary statistics. For the main RDD analysis, we restrict our sample to 24 months just before and after the cutoff months. The cutoff month is September 1993 for high school enrollment, and September 1988 for other outcome variables. While the cohorts are a few years apart, we see differences in the later

life outcomes. As this table shows, college enrollment is lower for female high school graduates who were born after September 1988 than before. College enrollment is higher for men who were born after September 1988. Moreover, marriage and fertility rates notably increased among the young female cohort. In contrast, the difference in high school attendance rates before and after the 1993 cutoff are small. Since the around-1993 cohort is young, we do not keep track of their later outcomes and thus report the characteristics only for the around-1988 cohorts. These pieces of data features suggest that the quota may have affected young men and women's education as well as work and family decisions. The causal effect of limiting employment opportunities will be empirically tested in the empirical section.

### 3.3 Graphical Evidence

Before conducting the formal analysis, we provide informal evidence on how the quota affected the labor market opportunities. Figure 1 plots the proportion of female workers who are employed in the public sector in each calendar year. The left graph is for young women aged 19-24. We see a sudden drop in the employment rate in the year of the quota implementation. The right graphs show the fraction of women aged 25 to 28 employed in the public sector during the same time window with no dips. These graphs highlight that the quota in fact affected the employment rates in the public sector for the new hires, but not those who were already employed. Given that the public sector rarely fires workers, the quota did not directly affect those who were already employed in the public sector. As such, the ceiling is expected to have had a large effect on employment for those looking for public sector employment opportunities.

Figure 1: The 2010 Quota and The Rates of Female New Hires by Sector

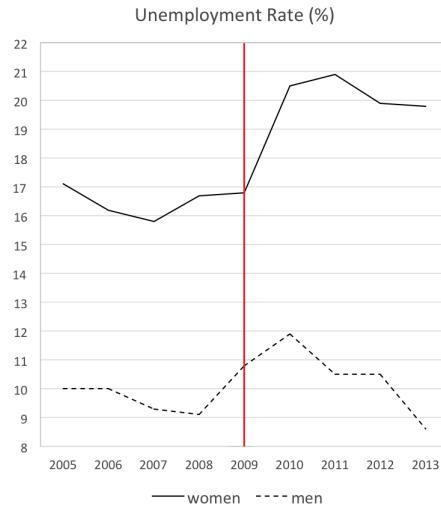

Notes: The left graph depicts the proportion (%) of women aged 19-24 who are employed in the public sector (=No. of women who observed that they are employed in the public sector/ No. of women in the corresponding age group in a given year); the right presents the same statistics for women aged 25-28. The abrupt reduction occurs only for the young workers, reflecting that the 2010 quota mainly affected new hires, not the existing employees in the public sector.  
Source: Calculation by the authors using Iranian Labor Force Survey (ILFS).

In fact, the change in total female public employment was small; after the quota was instituted, the proportion of female employment in the public sector slightly decreased from 18.1% to 16.9% (Source: Statistical Center of Iran). In contrast, the largest effects of the quota are found on the number of new female hires and on unemployment rates.

Figure 2 shows the female unemployment rates in our data sample sharply increased from 17% to 21% immediately after the quota was implemented. In contrast, there was no contemporaneous upward spike for men. While the unemployment rate did slightly increase in 2010, that increase is considered part of a trend because the male unemployment rate had already started increasing in 2008, and the increment in 2010 was smaller than in 2009. What is more, the unemployment rate for men has declined since 2010, but for women it has plateaued and remained high. These pieces of evidence suggest that the quota was effectively instituted and immediately reduced young women's labor market opportunities for new hires.

Figure 2: The 2010 Quota and Unemployment Rates by Gender

Notes: Figure shows that the female overall unemployment rates sharply increased from 17% to 21% immediately after the quota was instituted in 2010. There was no obvious contemporaneous upward spike for men around that time.  
Source: Calculation by the authors using Iranian Labor Force Survey (ILFS).

## 4 Empirical Strategy

The purpose of our empirical analysis is to identify the causal effects of limiting labor market opportunities on women's education decisions. Our main variable of interest is variation in how individuals perceive labor market opportunities caused by the quota. We address the endogeneity issue by utilizing age-at-school-entry policies in addition to province-level variation in treatment. We first apply the regression discontinuity

design (RDD) analysis by exploiting the fact that the year a person starts/end school is a discontinuous function of the birth month. Using the RDD, we examine the effects on education enrollment as well as the long-run effects on their later lifetime outcomes (e.g. their employment, wage, marriage, and fertility) of the same sample cohorts. We also apply the differences-in-differences (DID) estimation by exploiting how tightly the quota binds across province. The DID analysis helps us to evaluate the direct, immediate effects of the quota on outcomes other than education.

## 4.1 Regression Discontinuity Design

Our main strategy is a regression discontinuity design (RDD) that exploits a sharp cut-off across birth cohorts that divide the treated group and control group with respect to school attendance. An age-based discontinuity in our setup is considered exogenous for school enrollment, but not for other decisions such as labor market outcomes. Since individuals have flexibility with regard to when they will enter the labor market (e.g. some individuals may avoid the treatment by delaying graduation or attending graduate school), we cannot have a clear age cutoff that defines the control and treated group for outcomes other than education decisions. As such, we keep track of the same cohort whose education decisions are affected by the quota and examine the long-run consequences of the treatment on their later lifetime outcomes. The purpose of this analysis is to examine what happened to those who reduced education attainment as a result of facing lower labor opportunities due to the quota.

To be specific, in looking at the effect of the quota on attending high school, we use the birth cohort of September 1993 as the cutoff and consider those who were born between September 1991 and August 1993 as the control group and those born between September 1993 and August 1995 as the treated group. Concerning its effect on college attendance, we use September 1988 as the cutoff and consider those born between September 1986 and August 1988 as the control group and those born between September 1988 and August 1990 as the treated group. The sample size for high school enrollment is 176,431 and for college enrollment is 119,332.

We construct regression-adjusted differences by including smooth functions of age as well as controls for province and other factors. The general form of our estimated regression is as follows:

$$Y_{it} = \gamma_1(\text{Treated}) + g(\text{Birth Cohort}) + \mathbf{Z}'_{it}\mathbf{B} + \varepsilon_{it} \quad (1)$$

where  $Y_{it}$  is the education outcome for an individual  $i$  at a given time  $t$  (calendar year). The first term is the treatment cohort dummy (Treated birth cohort) on its own. The second term,  $g(\text{Birth Cohort})$ , is a smooth function of birth cohort. The

vector  $\mathbf{Z}_{it}$  contains a constant term and a set of individual specific characteristics that affect education outcomes (including parents' education, province dummies, rural-urban dummies, and time dummies). The coefficient  $\gamma_1$  of the birth cohort dummies captures the impact of the quota. This method enables us to identify the effect of the quota on education by exploring the discontinuities between the treated and the control cohorts.

Specifying the smooth function of birth cohort requires caution since the estimated treatment effect may be sensitive to how the smooth function is estimated. For the main analysis, we present estimates of the linear spline model (separate regressions on both sides of the discontinuity) with a small window around the birth cutoff year. To be specific, we use the following regression as the baseline model:

$$Y_{it} = \gamma_1(\text{Treated}) + \delta_1(\text{Cohort} - \text{Cutoff}) + \delta_2(\text{Treated}) \times (\text{Cohort} - \text{Cutoff}) + \mathbf{Z}'_{it}\mathbf{B} + \varepsilon_{it} \quad (2)$$

In the Appendix, we re-conduct the analysis using different specifications for the smooth function (including standard linear, quadratic, and cubic functions, as well as quadratic splines) and check robustness. Further, we also show estimates of the linear spline model for various size of bandwidth to check the sensitivity of our results.

Since the policy variation occurs at the education cohort level, we cluster the standard errors by birth quarter and province based on the entry age cutoff rule. That is, with September cutoff adopted in Iran, we group the individuals who were born between September and August in the following year into the same cohort because they enter a school program together. This approach is equivalent to the method that collapses the individual-level data into education cohort group ([Lee and Card \(2008\)](#)).

The assumption that  $g(\cdot)$  is a continuous function means that difference in labor market opportunities are the only source of discontinuity in outcomes around the cutoff cohort. Potential confounding factors could include other policies that affect the control and treated cohorts differently. However, this concern is mitigated by the fact that no other education or labor policies were implemented in 2010 and that no earlier policies or events affected the cohorts around the cutoff differently. Furthermore, as we will show in the result section, we examine if other confounding factors drive the estimates by using pre-reform data. Specifically, we investigate whether there was any discontinuity in employment and education outcomes using the corresponding age group of older cohorts in the sample years before the introduction of the quota. Using the pre-reformed data, we find no significant changes across the birth cohorts. The details will be discussed in the later section.

## 4.2 Differences-in-Differences

In addition to the education outcomes and long-run effects, we are interested in how the quota affected the economy overall. To do so, we conduct the DID analysis. We study not only spillover effects to the private sector and men's employment outcomes but also women's employment, marriage, and fertility.

Denote outcome variables as  $Y_{ijt}$  for an individual  $i$  in province  $j$  at a given time  $t$ . For each outcome, we conduct regression analysis using the following baseline specification:

$$Y_{ijt} = \gamma Post_t \times \bar{D}_j + \alpha \bar{D}_j + \lambda_t + \varphi_{rt} + \mathbf{X}'_{ijt} \mathbf{B} + \varepsilon_{ijt} \quad (3)$$

where  $Post_t$  is the dummy which is equal to 1 after 2010 and 0 otherwise. The first term is the treatment intensity measure in province  $j$  ( $\bar{D}_j$ ) with the interaction term of the post-treatment period dummy ( $Post_t$ ). The second term is the intensity variable on its own. The third term,  $\lambda_t$ , is a vector of time effects to control for changes in macroeconomic conditions of the overall Iranian economy. We allow the time effects to differ between urban-rural regions by adding region-year fixed effects,  $\varphi_{rt}$ . Note that region-year effects can capture changes over time that affect countries within a region similarly and thus control for changes in demand and/or supply of the regional labor market. The vector  $\mathbf{X}_{ijt}$  contains a constant term and a set of individual specific characteristics that affect outcome variables, including age, regional dummies, and family background (parents' education). The last term,  $\varepsilon_{ijt}$ , is the error term. Under some assumptions, the estimated coefficient  $\gamma$  captures how the quota affected the outcome of our interest. In running the above regression analysis, we look at the difference in treatment intensity across all provinces before and after the policy change. Instead of having a clear-cut control group, we examine how people behave differently among the differently affected provinces.

We measured the treatment intensity of the 2010 quota by the pretreatment share minus the target hiring rate of women in the public sector. Specifically, the intensity for province  $j$  is measured in the percentage difference between the pretreatment employment share in 2009 and the target hiring rate of women in 2015 in the public sector:

$$\bar{D}_j = \frac{(\text{Share of women in the public sector in 2009}) - (\text{Share of women in new hire in 2015})}{\text{Share of women in the public sector in 2009}}$$

Ideally, we wish to measure the intensity using the data in 2009 and 2010. However, detailed information of the quota was not available until 2015. We use the data from 2015 to infer the quota in 2010. Thus, in applying this proxy, we need to assume that the quota system did not change (the proportion of female job openings is the same in each province) between 2010 and 2015. In the Appendix, Table B.2 reports

the summary statistics of the intensity measurements. To check robustness, we use two other measurements of treatment intensity and report the results in the Appendix, Table D.7.<sup>7</sup>

Unlike the RDD analysis, this approach requires stronger assumptions that the variation in the treatment intensity needs to be exogenous. We check the possible endogeneity problems and find no evidence of systematic relationship between the treatment and confounding factors. The analysis is summarized in subsection 5.3 and presented in detail in the Appendix.

## 5 Estimation Results

We analyze the impact of this hiring quota using the RDD method and then report the effects using the DID method. After that, we summarize robustness check analysis and address endogeneity concerns. We discuss the findings at the end of this section.

### 5.1 Regression Discontinuity Design Estimates

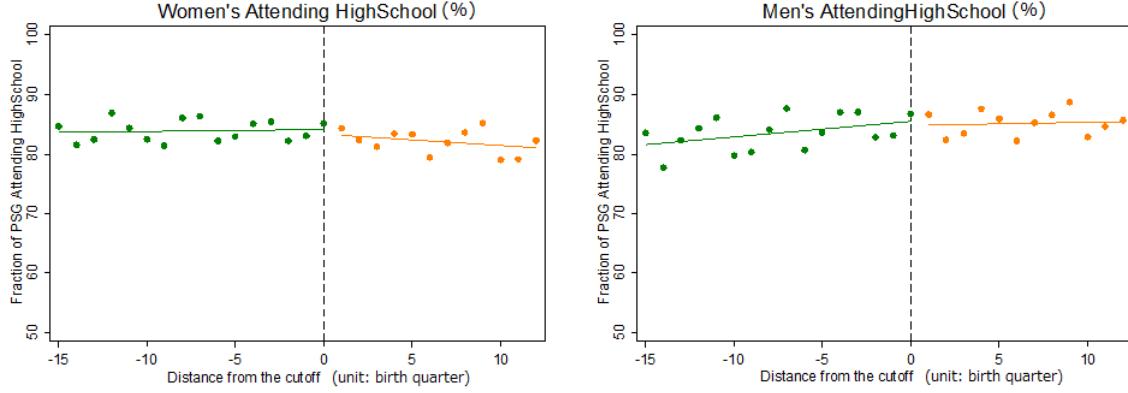

We first look at the effects on education using RDD. We also apply the RDD to estimate the effects on outcomes other than education and interpret the results as the long-term effects of the quota (through the channel of education effects). In presenting the analysis on education outcomes, we focus on high school attendance and college attendance. Since education up to the 9th grade is compulsory in Iran, we expect the quota affects enrollment in high school and/or higher education, if any. We first examine the effects on high school attendance rates.

Figure 3 and the first two columns of Table 2 present the effects on high school attendance rate for age 15-18 by gender. We find that high school attendance rates remain similar before and after the quota for both genders. We conclude that reduced labor market opportunities in the public sector did not significantly affect individuals' decisions on high school attendance. If the quota induces more dropouts before entering college and reduces the proportion of high school graduates, it is hard to separate the effects on college attendance from those on high school or earlier education for some of the treated cohorts. However, we find no such effects.

---

<sup>7</sup>We provide support for this assumption in two ways. In the official document, it is written that the quota policies did not change once they were implemented. The new regime, which disclosed these data sources, publicly admits that the current hiring situation is discriminatory, and they are considering reverting to the policies prior to 2010 (Source: Interview with vice president in 2015). We contacted the government agency in an attempt to collect more data. The officers told us they cannot disclose the information of the quota prior to 2015, but confirmed that there was no change in the quota policies or the resulting female proportion for the new hires.

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth quarter-province level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified education level. The sample is men and women aged 15 to 18 who are eligible for enrolling in high school and aged 19 and 20 who complete high school and are eligible for enrolling at any university programs. Control variables are individual and family characteristics including age and parent's schooling. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification.

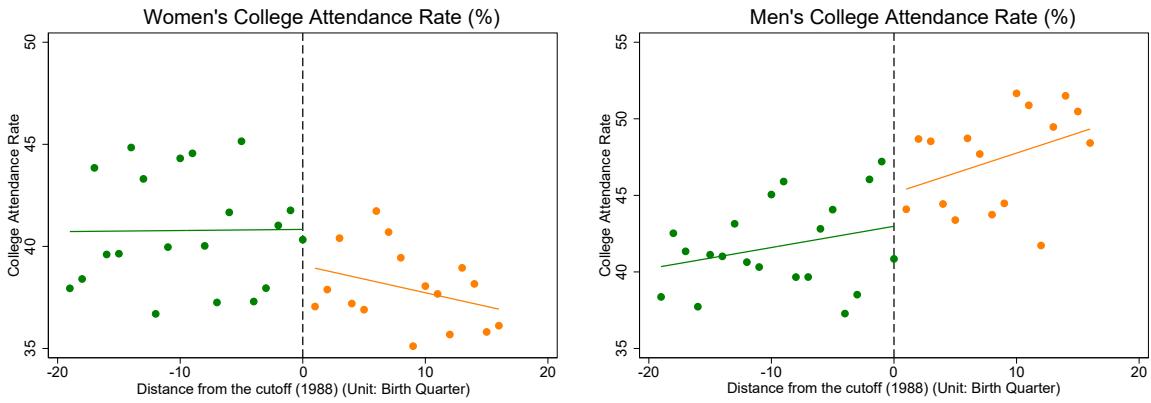

Figure 4 shows the attendance rate of a university program for age 19-20 by gender.<sup>8</sup>

The denominator is the number of high school graduates in each birth quarter and the numerator is the number of individuals who ever attended college. Since we find no

<sup>8</sup>The university program defined here includes 2-yr and 4-yr programs

changes on high school attendance, we hereafter suppose that there is little composition change in the population of individuals who are eligible for attending college. Unlike the effects on high school attendance, we see a sharp decline in women’s college attendance rate at the cutoff. Note that the college attendance rate trends downward for the treated cohort while trends upward for the control cohort. This trend change shows that younger cohorts reacted more strongly to the employment ceiling, which indicates that younger cohorts have more time to make adjustment to a reduction of labor market opportunities.

Figure 4: Effects of the Employment Quota on College Attendance Rate (at Age 19-20) by Gender

*Source: Calculation by the authors using Iranian Labor Force Survey (ILFS).*

Table 2 reports the main estimation results of an RDD analysis. We report the results when allowing trend changes in Columns (2) and (4). As expected from Figure 4, the college enrollment rate of women decreases (by 3-3.2 percentage points) and the slope change is estimated as negative for women, indicating that the adverse effect is larger for younger cohorts. We find men’s college attendance rates significantly increase, but to a lesser extent than women’s decrease. The men’s attendance rate increases by 2.0 percentage points.

To examine whether the estimates in fact capture the effect of the quota on college attendance, we conduct placebo tests by using the pre-reform data (1977-1985) and presented the results in Columns (4)-(8) in Table 2. The estimated effects are found insignificant, indicating that the estimated effects are driven by the quota, not by confounding factors.

Now, we look at the outcomes other than education using the RDD and investigate the indirect effects of the quota through the channel of education effects. We apply the same cutoff to define the treated and control group that are directly affected by the quota with respect to their education decisions. We investigate the consequences of

the treatment on the later lifetime outcomes such as employment, wage, marriage, and fertility.

|                       |                           |                     |                    |                           |                   |                  |                           |                   |
|                       |                           |                     |                    |                           |                   |                  |                           |                   |
|                       |                           |                     |                    |                           |                   |                  |                           |                   |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth quarter-province level in parentheses. The dependent variable is an indicator for job market statuses. The sample for this analysis is women aged 23-29 because in fact, most individuals at these ages have completed. Control variables are individual characteristics including age and schooling. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification.

Table 3 presents the impact on labor market outcomes. Note that we still use September 1988 as the cutoff that determines the treated and the control groups (re-

garding whether the quota affected college attendance decisions) and look at employment outcomes at age 23-29. The first six columns present the effects on employment status. The results show that the treated female cohort has a significantly higher unemployment rate and lower employment rate. The last two columns present the effects on wages for each gender-education group. We find no significant effects. This finding is no surprising given that women accounted for a relatively small fraction of the Iranian labor force. In the bottom part of the table, we look at employment outcomes in the public and private sector separately in order to examine spillover effects across sectors. The results indicate that the quota affected employment rates of women and men in the public sector, but there were no spillover effects observed in the private sector. Figures 5 and 6 show the corresponding graphs.

Figure 5: Effects of the Quota on Employment in the Public Sector by Gender

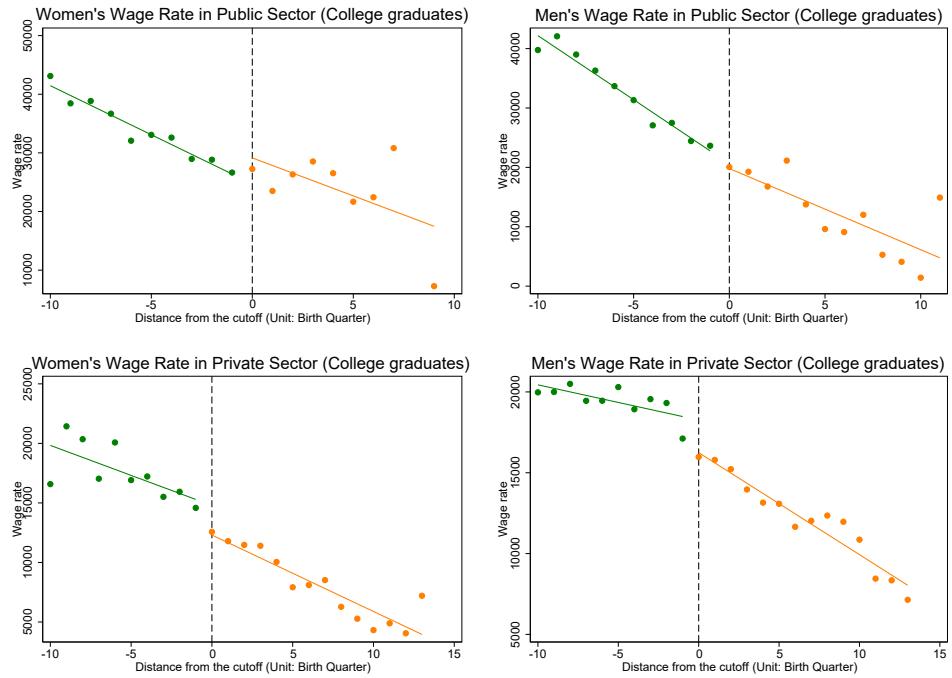

Source: Calculation by the authors using Iranian Labor Force Survey (ILFS).

Figure 7 shows the impact on marriage for women and Table 4 presents the corresponding regression results. The first two columns look at the marriage rates for 18-24 year-old women and the last two columns present the ones for 25-27 years old women. Although not large, we find that the quota significantly increased the marriage rates of women aged 18 to 24 while it had no significant effect for women aged 25-27 or for men.

Table 5 presents the impact on fertility. We use the number of children as the dependent variable. As in the results for marriage, the first two columns look at younger women aged 18 to 24 and the last two columns look at women aged 25-27. Again, we find that the quota significantly increased fertility for the younger women but no significant effects for the older women. The estimates capture the indirect effect on marriage or fertility rates since the quota reduces the gain from education and labor market participation, which in turn reduces the opportunity cost of the alternative (often exclusive) options such as household work and childbearing/childrearing. Figure 8 shows the corresponding graphs for age 18-24.

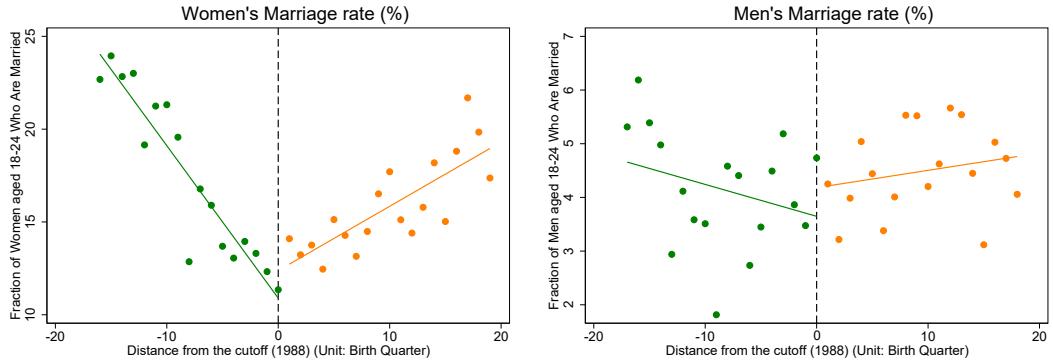

In sum, we find that reduced employment opportunities greatly decreased women's college attendance rate, slightly increased men's college attendance rate, and slightly

Figure 6: Effects of the Quota on Wage by Gender (College Graduates)

Source: Calculation by the authors using Iranian Labor Force Survey (ILFS).

increased women's marriage rate. These analyses imply that some of women who did not enroll in school after the quota are less likely to be employed, but are more likely to get married young and have a child.

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth quarter-province level in parentheses. The dependent variable is number of children. Control variables are individual characteristics including marital status and schooling. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification.

## 5.2 Differences-in-Differences Results

We apply the DID analysis to compare the immediate effects of the quota on employment opportunities, marriage, and fertility as well as education. We also look at the employment effects in the private sector and the effects on college major decisions.

Table 6 reports the effects of the quota on labor force participation, employment, and unemployment for women (Panel A) and men (Panel B). We divide the sample of each gender group by education attainment and look at employment outcome at age 23-29. In the first six columns, we look at the immediate impact on the rates of labor force

Figure 8: Effects of the Employment Quota on Fertility (Age 18-24)

Source: Calculation by the authors using Iranian Labor Force Survey (ILFS).

participation, employment, and unemployment by education. The dependent variable is a dummy for employment status. We find no significant employment effects for men and women with high school education. For college-educated women, the coefficient of our interest is significantly different from zero for the outcomes of labor force participation and employment; they are estimated as -0.015 and -0.016, respectively. The numbers indicate that a 1 percentage-point decrease in the proportion of female hiring resulted in a 1.5 percentage point decrease in the propensity toward labor force participation and a 1.6 percentage point decrease in the employment propensity (as reported in the table). Since the mean of the treatment intensity is 11.3, these results show that the quota reduced the probability of labor force participation and employment for female college graduates by 16.95 percentage points ( $=1.5 \text{ percentage points} \times 11.3$ ) and 18.08 percentage points ( $=1.6 \text{ percentage points} \times 11.3$ ).

We find no significant spillover effects of the quota on the labor market for non-college graduates. Such findings are consistent with the labor market structure in Iran, as Iran's labor market segregation by education is very strict. Companies often establish positions based on workers' education level. For the jobs that require a certain level of education, only applicants with that level of education are permitted to apply, e.g. applicants with a master's degree are not allowed to apply for a job that requires a bachelor's. What is more, the Iranian law sets the minimum wage according to education attainment, and educated people cannot work for a wage lower than the education-specific minimum wage (Source: Iranian Labor law, Ministry of Cooperative, Labor and Social Welfare). Even if college educated workers are willing to work for low wages, the labor market arrangement does not allow them to do so.

For men, we find that the quota increased employment and decreased unemployment. Such results are somewhat surprising given that the proportion of female workers in the

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the province-year level in parentheses. The dependent variable is an indicator for whether an individual participated in the labor force (LFP), whether an individual had a job (in the public/private sector) (Empl.), and whether an individual was unemployed (Unemp.). \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. LFP stands for labor force participation.

entire economy is not large; women's share of employment in the public sector in the pre-treatment period is about 20%.

In the bottom part of the table, we look at employment outcomes in the public and private sector separately in order to examine spillover effects across sectors. For college-educated women in the public sector, the coefficient of our interest is estimated as -0.9 (percentage points) for the propensity toward employment. The estimate means that a 1 percentage-point decrease in the proportion of female hiring in the job posting in the public sector in fact resulted in a 0.9 percentage point decrease in the actual actual employment propensity for young women in the public sector. It instead leads

to a 1.4 percentage point increase in young men's employment propensity in the public sector. For others, the estimates show insignificant effects. In theory, it is possible that the private sector would react to the situation and hire more college graduates because more female educated workers were unemployed and seeking a job opportunity after the quota. However, the results indicate that there were no spillover effects observed in the private sector, which is consistent with the RDD results.

Table 7 reports the estimates for education and marriage outcomes. The results are presented for each gender. The first two columns present the effects of the treatment on education. As for education, we find that women's enrollment in university significantly decreased by 1.9 percentage points if a proportion of female hires in the public sector decreases by one percentage point. This result indicates that the college enrollment rate decreased by 21.47 percentage points ( $=1.9 \text{ percentage points} \times 11.3$ ) for the province that experienced a 11.3 percentage point reduction in the share of female hires. These findings imply that the quota had significant effects on women's college enrollment. The last four columns in the same table present the effects of the treatment on marriage. The dependent variable is a dummy for being married. Our analysis indicates that a slight increase in male employment in the public sector driven by the quota was big enough to increase men's college attendance by altering men's perspective toward the labor market opportunities.

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the province-year level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified educational institution. Control variables are year and province fixed effects, rural-urban dummies, birth year, and family background including parent's education.

\*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. We also conducted the analysis by excluding observations in 2009, but the results are similar.

The sample for this analysis is men and women aged 14 to 25 who are eligible for enrolling in high school and aged 18 to 35 who complete high school and are eligible for enrolling at any university programs.

Table 8 presents the effects of the treatment on fertility. The dependent variable is the number of children. Unlike the RDD estimates, we found insignificant effects on fertility outcomes at any age level, but the signs of the estimated coefficients are all positive and the same. Such differences across estimation methods can be explained by a relatively large standard error in the DID estimates. Instead of the number of children, we also look at the effects on age of the first childbirth and the probability of having a child in a given year, but the effects are found insignificant. Due to the data limitations, we cannot conclude that there are no significant effects on fertility related outcomes. Given that it takes a longer time for these outcomes to react to labor market shocks, we need a longer period of data to make a conclusion.

Table 8: DID Results (Women's Fertility)

| Dependent Var. | Num. Children  |          |         |         |         |
|----------------|----------------|----------|---------|---------|---------|
| Mother's Age   | All (under 45) | under 25 | 26-30   | 31-35   | 36-45   |
| Treatment      | 0.023          | 0.011    | 0.049   | 0.066   | -0.003  |
| $\gamma$       | (0.123)        | (0.052)  | (0.074) | (0.156) | (0.164) |
| Observations   | 871,080        | 137,027  | 179,848 | 194,264 | 359,941 |
| R-squared      | 0.344          | 0.252    | 0.242   | 0.231   | 0.170   |
| Mean Control   | 2.200          | 0.980    | 1.653   | 2.356   | 2.847   |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the province-year level in parentheses. The dependent variable is the number of children unconditional and conditional on age. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. We also conducted the analysis by excluding observations from 2009, but the results are similar.

Overall, the results are consistent with the RDD estimates except in the case of fertility outcomes. While we find significantly positive effects using RDD, we did not find any effects on fertility at any age level.

To further highlight the importance of labor market opportunities for women as a determinant of their educational attainment, we also examine whether the quota decreased the proportion of female students in college majors with strong ties to public employment and increased college majors with weaker associations to the public sector.

Table 9 presents the effects on choice of college major. The dependent variable is an enrollment dummy for each college major at four-year universities. The results show that women do not enroll in college majors that are highly related to public sector employment, but undertake other fields that are less related to public employment. College majors that are highly relevant to public employment are engineering, health, and science majors. All of these majors experienced a larger drop in women's enrollment in more affected provinces. For example, as the intensity measure increased by 1 percentage point, women's propensity for choosing an engineering major decreased by

0.097 percentage point. That means that, in the province where the quota decreased the female share by 11.3 percentage points, the number of women majoring in engineering decreased by 1.10 ( $=0.97 \text{ percentage point} \times 11.3$ ) percentage points. While the analysis on college major provides us compelling results, we do not apply an RDD analysis due to the small sample size.

Table 9: Effect on Education by Gender and College Major

| College Major         | Engineer. | Health   | Science  | Arts     | Education | Business | Agri.   | Service |
|-----------------------|-----------|----------|----------|----------|-----------|----------|---------|---------|

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the province-year level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified educational institution. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification.

The sample for this analysis is men and women who are enrolled in college during the study period.

### 5.3 Robustness Check

Our findings are robust to a number of choices made in the analysis. We briefly summarize the results from robustness checks here. The detailed robustness check results for RDD are reported in the Appendix, Tables C.3 to C.6 and the robustness check for DID are presented in the Appendix, Tables D.7 to D.11.

As for the RDD analysis, we examine the sensitivity of our estimates to different bandwidths, model specifications and sample periods. First, concerning sensitivity to bandwidth, we use the cohorts that are only a few years apart and obtained similar results with slightly larger standard errors. The results show the main results are robust to the bandwidth choices presented in the Appendix, C.3. We check sensitivity to model specifications by comparing the results with and without control variables and find that the estimated coefficients of the interaction terms are qualitatively the same regardless of the inclusion. These results are also found in the Appendix, Table C.3. Second, we check that our results are robust to different model specifications. The detailed results are found in the Appendix, Tables C.4 to C.6. Again, we find results qualitatively similar to the ones in the main analysis; the signs of the coefficients and

significance are all the same. Third, as to sample periods, we use the data until 2015 for the analysis reported in the main section. We re-conduct our analysis by limiting our sample to a shorter period. In doing so, we show evidence that our findings are not driven by other policies instituted around the time of the quota implementation.<sup>9</sup> Shortening the sample periods limits our ability to analyze the long-run effects of the quota, but we confirm that the main estimates on school attendance are qualitatively the same.

Other important changes in policies and economic conditions are the population control implemented in 1979-93 and economic sanctions. However, these changes affect the Iranian economy much earlier than 2010 and if there is any impact, both control and treated cohorts are affected in a similar fashion. The best evidence for this is the RDD estimates using the pre-quota periods, which are found significant as presented earlier in the main section in Tables 2 and 3. In sum, the above tests build confidence in the accuracy of our findings.

As for the DID analysis, we first check the sensitivity of the DID results to the measurement of treatment intensity. We apply two other measurements for treatment intensity. Regardless of the variable definition, we find qualitatively similar results to the ones reported in the main section except for fertility outcomes. As for fertility, the estimated effects became insignificant/significant, depending on model specifications when using the alternative measurements, but the directions of the estimated effects are consistent. The results are presented in the Appendix, Table D.7.

We examine that the treatment intensity is not correlated with confounding factors and present the data features to support exogeneity of the treatment. We first check whether the more affected areas are comparable to less affected areas. To do so, we regress the treatment intensity on province characteristics to show that our treatment is not associated with other economic conditions that affect the outcomes of our interest (See Table D.8 in the Appendix). We also show no significant differences in observable province-specific characteristics in the periods prior to the quota (See Table D.9 in the Appendix). We also re-conduct the analysis on employment and education by excluding observations in the election year 2009.<sup>10</sup> Without observations in 2009, the effects on

---

<sup>9</sup>There are two important policies to which we must pay attention; a policy that changes the composition of college majors announced and implemented in 2012, and policies aiming at increasing fertility announced and implemented in 2015. We use 2006-2011 and 2006-2014 in the robustness check analysis.

<sup>10</sup>The Iranian economy was affected by the presidential election from late 2008 to mid 2009. As is often the case with elections, employment surged during the election period and the published statistics might have been misreported in favor of the incumbent president. The election period ended on June 12, 2009, when the incumbent president Mahmoud Ahmadinejad won election for the second time. The election results were upsetting to many people in Iran, who had supported opposition candidates, and resulted in large-scale protests. However, the major turbulence caused by the protests had ceased by December 2009. The election results are not likely to change the long run economic trend during 2006-2015 largely because Ahmadinejad's policies in the second term were similar to his policies in the first term.

employment for college-educated women are still significantly negative with a magnitude of -0.41 (percentage points), which was previously estimated and reported in the table as -0.33 (percentage points). Other estimates are found to be very similar in all the results.

We also address possible estimation bias due to other policy changes. To examine if any other policy drives differences in trends, we conduct placebo tests. We find no evidence of difference in preexisting trends across provinces. We also re-conduct the analysis on employment and education by excluding observations in the election year 2009 and find similar results.<sup>11</sup> More formally, we conduct a placebo test for education outcomes by using the timing different from the actual timing of the policy implementation as the treatment year. We find that none of the coefficients are significantly different from zero. We thus show that there are no obvious anticipatory effects or no violation of the common trend assumption (See Table D.10 in the Appendix). These results provide additional support for the key assumption that there was no particular systematic trend change that affected education outcomes across provinces other than the 2010 quota.

## 5.4 Summary and Discussion

In both the RDD and DID analysis, we find significantly negative effects on (college educated) women's labor force participation and employment and significantly positive effects on women's unemployment rates. For men, the effect on each labor market outcome is found opposite to that of women. Thus, we confirm that the quota indeed reduced labor market opportunities for women and there was a small, yet non-ignorable spillover effect into men's labor market.

In contrast, spillover effects of the quota on the labor market for non-college graduates are insignificant. The reduced employment opportunities for college graduates resulted in significant reduction of women's enrollment in university, but not for other education levels. We also find no spillover effects to the private sector.

The findings for education, marriage and fertility are in accordance with those in Jensen (2012), which estimates the effects of higher perceived job opportunities using Indian data. He finds a 2.8 percentage-point increase in enrollment rates of any college when labor force opportunities for women increased. He also finds that women aged 15 to 21 in treated villages were 5.1 percentage points less likely to get married during the three years after they were exposed to more job opportunities. As for fertility, while he could not study the long-term effect due to data limitations, he documents that women who are exposed to more job opportunities reported wanting to have 0.35

---

<sup>11</sup>Note that 2009 was election year and employment typically increases in an election years because the Iranian government usually attempts to increase its vote share and hence its re-election probability.

fewer children in their lifetime. In either outcome, the magnitude of the impact is larger in Jensen's paper than ours. Such a difference in results makes sense considering that Jensen's randomized experiment is conducted in rural areas in India while the policy of our interest mostly affected urban areas where the public sector jobs are more concentrated. Overall, our findings add to his work showing symmetric effects of positive and negative shocks to labor market opportunities: while he finds increasing labor market opportunities increase education, our paper finds decreasing labor market opportunities decrease education.

## 6 Conclusion

We investigate how limiting the number of job openings for female workers affects young women's education attainment, work, and family decisions. To do so, we exploit a quasi-natural experiment setup in Iran, whose government has restricted the number of new female hires in the public sector since 2010. By exploiting this policy change regarding Iranian female workers, we find that limiting labor market opportunities for women adversely affects women's education. We also find that the quota significantly affected women's college major choices. While the proportion of female students in college majors with strong ties with public employment decreased, it increased in college majors with weaker associations to the public sector. Instead of attending college, those women who see lower opportunities in the labor market are more likely to get married and have a child. Our analysis indicates that the anticipation of labor market returns is particularly important for the investment of human capital and subsequent lifetime decisions.

In sum, this paper contributes to the literature that assesses how changes in the labor market affect decisions on education by providing a causal estimation. Needless to say, understanding the role of employment opportunity in education decisions is important for many settings and policies since education is associated with economic growth, reduced crime rates, better health, and higher social welfare. Our findings suggest that policy makers who would like to influence education outcomes must simultaneously address the labor market opportunities that students face after graduation.

## Appendix

### A Article 230 of the National Five-Year Development Plan

Article 230 of the fifth development plan states that “The government and all ministries and organizations, including the Center for Women and Family, are formulating a comprehensive national development program on women and family. The plan aims at strengthening the family foundation; review of the laws and regulations; prevention of social damages; economic development; creating home-based jobs for female head of household; social security; empowerment of civil society, and the reform of women’s machineries.” (Source: Sixty-sixth Session of the United Nations of General Assembly on October 11, 2011; Shargh newspaper. Number 2568. Tuesday, April 26, 2016 Sharghdaily.ir/News)

Note that while the document provided by the United Nations only mentioned “creating jobs for female head of household,” as one of the development goals, other documents circulated in Farsi clearly state “creating home-based jobs for female head of household and low-income women”.

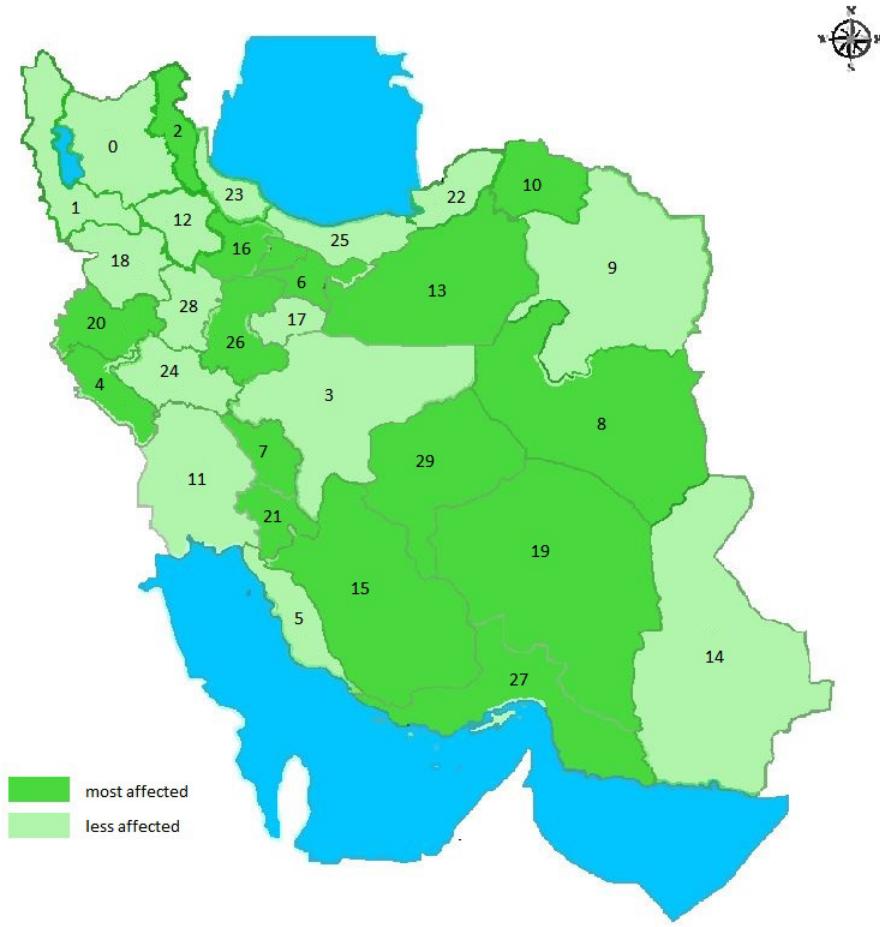

### B Treatment Intensity

The proportion of female employment in the public sector by province before and after the ceiling is presented in Figure B.1 and Table B.1. Although there is a province, Qom, whose hiring proportion in 2015 exceeds the proportion of female employment in 2009, this province is not a representative Iranian province in the sense that this area is the center of the Shiite sect of Islam and most religious schools are concentrated in this city. The gender segregation in this city has been very high traditionally; e.g. The University of Qom has two campuses: one for male students and the other for female students and two administrative offices for employees of each gender (Source: The website of The University of Qom (<http://www.qom.ac.ir/Portal/Home/>)). The University of Qom is one of the few universities in Iran that supports gender segregation. Administrative and

educational environments are separated for women and men. The University of Qom has two separate campuses for women and men. (translated from Farsi to English by the authors. This description can also be found in the Farsi version; the English version does not contain the corresponding expression) The hospitals in Qom Province practice gender-segregation, and there are hospitals which employ only women. For example, Shahid Beheshti hospital in Qom is the first hospital to support gender segregation. In this hospital, women have been treated only by female physicians and men have been treated only by male physicians. Partly due to a large degree of gender segregation, this province had the lowest proportion of women in the public sector before the quota (17%), and the proportion did not decrease because the female-only sector needs to keep women employees in order to operate its gender-specific organizations (schools or hospitals). While this province is the exception, the raw data for the rest of Iran exhibits a drop both in employment size and the proportion of female workers in the public sector.

Given that treatment intensity across provinces are driven by the share of gender-segregated workplaces, which are exempted from the quota, a major concern is the distribution of hospitals and schools may be correlated with province-specific characteristics. However, we find no such correlations, as discussed in the main section. In addition, we here discuss that the treatment intensity is not correlated with the population or geographical areas. Tehran Province, which includes the capital Tehran, was among the most affected provinces: the proportion of women in 2009 was 20.7% but the proportion of job openings for women (including the job openings for both genders) was only 1.9% in 2015. Isfahan, the second most populated city after Tehran, was among the less affected provinces: the proportion of women was 26.6% in 2009 and the proportion of job openings in 2015 was 23.9%. On average, the proportion of women is 25% in the pre-treatment periods, but only 10% of job openings were open to women after the quota was imposed. The proportion of female new hires in the public sector decreases by 11.3 percentage points on average. Table B.2 reports the summary statistics of the intensity measurements. To report the summary statistics of treatment intensity, we divide the sample into two subgroups according to treatment intensity (below median or above median). The less affected province group includes all working-age individuals in the provinces with treatment intensity below median. The more affected province group includes all working-age individuals in the provinces with treatment intensity above median.

Figure B.1: Map of Iranian Provinces showing the Intensity of the 2010 Hiring Quota

Notes: Less affected provinces are the provinces with treatment intensity below median.

More affected provinces are the provinces with treatment intensity above median.

Source: Calculation by the authors using the data of job openings in each province in the public sector in 2015

## C RDD: Robustness Checks

### C.1 Sample Universe

Cell size and sample composition for men and women in the data are shown in Figure C.2. The key identification assumption is that the treated birth cohorts are not systematically different from the untreated birth cohorts in other characteristics. The assumption is violated if there is a systematic change around the 1988 birth cohort cutoff. While the true age of an individual is predetermined, it is conceivable that some people could find ways to incorrectly report their age by falsifying their birth certificates. To see if such manipulations were possible, we check the distribution of birth month. It is true that we see several spikes in August of each year, but no trend changes around the cutoff. The spikes (the higher density) are attributed to the parents' misreport about

Table B.1: The proportion of female employment in the public sector by province before and after the ceiling

| Province code | Province                   | % women in the public sector in 2009 (before the policy) | % job openings for women in 2015 (after the policy) | bind |
|---------------|----------------------------|--|---|------|

| 27            | Hormozgan                  | 27.76  | 10.66   | 1    |
| 28            | Hamedan                    | 27.31  | 25.47   | 1    |
| 29            | Yazd                       | 29.17  | 10.88   | 1    |

Notes: the province code corresponds to the code in Figure B.1. The indicator “bind” takes 1 if the share of female new hires in the public sector is smaller in 2015 than that in 2009.

their children’s birth of month in an attempt to send them to school earlier (since those who were born in September or later will go to school in the following year compared to those born in August). As seen from the graphs all of these patterns are stronger for the older cohorts because misreporting the birth date became more and more difficult recently. These trend changes happen gradually and there is no obvious gap before and

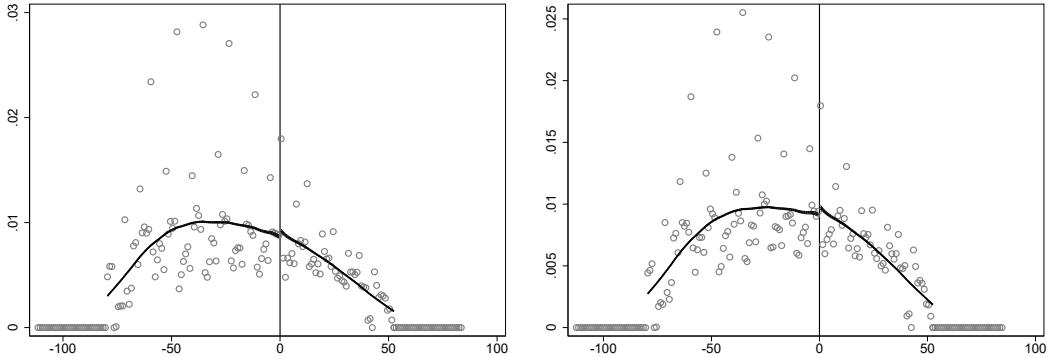

Table B.2: Descriptive Statistics: Treatment Intensity

| Variable   | Obs | Mean | Std. Dev. | Min  | Max  |
|--|-----|------|-----------|------|------|
| Intensity Measurement (%)                          | 29  | 44.6 | 23.2      | 6.7  | 91.0 |
| Intensity Measurement 2                            | 29  | 11.3 | 6.3       | 1.8  | 25.8 |
| Intensity Measurement 3 (%)                        | 29  | 0.6  | 0.5       | 0.06 | 3.2  |
| % of Female Workers in the Public Sector in 2009   | 29  | 25.2 | 3.7       | 18.9 | 35.9 |
| % of Female New Hires in the Public Sector in 2015 | 29  | 13.9 | 5.9       | 1.9  | 25.5 |

Intensity Measurement is measured as the percentage difference between the pretreatment share (% women in the public sector in 2009) and the targeted hiring rate of women in the public sector (% job openings for women in the public sector in 2015). This measurement is used for the main analysis. Intensity Measurement 2 is measured as (% women in the public sector in 2009-% job openings for women in the public sector in 2015). This measure is used for robustness check. Intensity Measurement 3 is measured as % job openings for women in the public sector in 2015 divided to the population of women at working age in 2015. This measure is also used for robustness check.

after the 1988 cutoff (it is no surprising because at that time their parents did not know there would be a quota policy in 2010). Thus, we do not observe systematic changes in birth rates before and after the cutoff.

Figure C.2: Distribution of Birth Months by Gender

## C.2 Different Bandwidth and Different Model Specifications

We examine the sensitivity of our RD estimates to different bandwidths. As presented in the first four columns of Table C.3 , we use the cohorts that are only a few years apart and obtained similar results with slightly larger standard errors. Thus, the main results are robust to the bandwidth choices. Next, we check the robustness of our results by comparing the results with and without control variables. The results are presented in the last three columns of the same table. The estimated coefficients of the interaction terms are qualitatively the same regardless of the inclusion.

For the discrete outcomes, we also estimate limited dependent variable models.

Table C.3: RDD Estimates with different bandwidth and controls (Education)

|                    | Attended college (cutoff=September 1988) |                      |                      |                      |                      |                      |                      |
|--------------------|--|----------------------|----------------------|----------------------|----------------------|----------------------|----------------------|

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth cohort level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified education level. Control variables are individual and family characteristics including age and parent's schooling. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification.

In the row "Trend shift," we present the estimated coefficient of the interaction term,  $Treated \times (BirthYear - Cutoff)$ . In the row "Pre-trend," we present the estimated coefficient of the cohort trend term,  $BirthYear - Cutoff$ .

Again, we find very similar results as the ones using a linear probability model; the signs of the coefficients and significance are all the same. We re-conduct the analysis

using different specifications for the smooth function. Table C.4 presents three different specifications, including the linear spline model, which is presented in the main section. The estimates are qualitatively similar in all specifications.

### C.3 Adding Treatment Intensity to RD models

An RDD estimate will be contaminated in our setting if any other factor that affects those who were born before and after the cutoff differently. We re-conduct the RDD analysis using the following specification:

$$Y_{it} = \gamma_1(\text{Treated}) + \gamma_2(\text{Treated}) \times \bar{D}_j + \alpha \bar{D}_j + g(\text{Age}) + \mathbf{X}'_{it} \mathbf{B} + \varepsilon_{it} \quad (4)$$

where we add the treatment cohort dummy with the interaction term of the treatment intensity measure in province  $j$  ( $\bar{D}_j$ ) and the treatment intensity on its own to the main specification. In particular, the coefficient  $\gamma_1$  of the birth cohort dummies captures the overall impact of the quota and the coefficient  $\gamma_2$  of the interaction term captures the effects multiplied by the intensity of the quota. This specification exploits the variation in not only across birth cohorts and time, but also across provinces.

Tables C.5 and C.6 present the results for education and marriage, which are similar to the main analysis using the regression discontinuity estimator. The finding implies that the main findings are robust to adding more controls (variation in treatment intensity).

## D DID: Robustness Checks and Falsification Tests

In this subsection, we present the data features to support exogeneity of the treatment. In particular, we show that the treatment intensity is not correlated with confounding factors. To show that the treatment is exogenous, we regress treatment intensity on province-specific characteristics.

### D.1 Measurement of Treatment Intensity

We check whether the results are different when applying different measurements of the treatment intensities. We try two other measurements for treatment intensity. One of the measurements is the proportion of women in the public sector in 2009 minus the proportion of job openings for women in the public sector in 2015 (Measure 2). Another measurement is the change in the number of public job positions divided by the working-age population for each gender in each province in order to reflect how competitive it was for women/men to acquire a job in the public sector (Measure 3). As for outcomes other

Table C.4: RDD estimates with different functional forms (Education)

|  | Attended college     |                      |                      |

| Treated × (Birth Cohort-Cutoff) | -0.009<br>(0.005)    | 0.004**<br>(0.002)   |
| Obs.                            | 93,616               | 54,130               |
| R-squared                       | 0.027                | 0.037                |
| Mean control                    | 0.812                | 0.425                |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth cohort level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified educational level. Control variables are individual and family characteristics including age and parent's schooling. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification.

than fertility, regardless of the variable definition, we find qualitatively similar results to the ones reported in the main section. Regarding fertility, the estimated effects became insignificant when using the alternative measurements while it was significant in the main analysis. The results are presented in Table D.7.

Table C.6: Adding Treatment Intensity to RD Models (Marriage & Fertility)

| Outcome                                | Marriage            | Number of children   |
|--|---------------------|----------------------|
| Treated                                | 0.024***<br>(0.004) | 0.004***<br>(0.001)  |
| Treated $\times$ Intensity             | -0.008<br>(0.007)   | -0.001<br>(0.001)    |
| Intensity                              | 0.030***<br>(0.004) | -0.001<br>(0.001)    |
| (Birth Cohort-Cutoff)                  | 0.050***<br>(0.001) | -0.004***<br>(0.000) |
| Treated $\times$ (Birth Cohort-Cutoff) | 0.035***<br>(0.002) | 0.004***<br>(0.000)  |
| Obs.                                   | 310,147             | 308,919              |
| R-squared                              | 0.029               | 0.030                |
| Mean control                           | 0.658               | 0.197                |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth cohort level in parentheses. The dependent variables are marriage (an indicator for whether an individual is married or not) and fertility rate (number of children). Control variables are individual characteristics including marital status and schooling. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. We also conducted the analysis by excluding observations in 2009, but the results are similar.

Table D.7: DID Results with Different Treatment Measures (Education)

| Intensity Measurement      | Measure1             | Measure2             | Measure3            |
|----------------------------|----------------------|----------------------|---------------------|
| <b>Panel A: Women</b>      |                      |                      |                     |
| Treated $\times$ Intensity | -0.019***<br>(0.004) | -0.001***<br>(0.000) | -0.327*<br>(0.182)  |
| Obs.                       | 296,063              | 296,064              | 296,065             |
| R-squared                  | 0.260                | 0.260                | 0.260               |
| <b>Panel B: Men</b>        |                      |                      |                     |
| Treated $\times$ Intensity | 0.038***<br>(0.004)  | 0.001***<br>(0.000)  | 0.659***<br>(0.176) |
| Obs.                       | 304,105              | 304,106              | 304,107             |
| R-squared                  | 0.263                | 0.264                | 0.265               |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth cohort level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified educational institution. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. The sample for this analysis is men and women aged 15 to 25 (18 to 35 for graduate school).

## D.2 Exogeneity of Treatment Intensity

Table D.8 shows that the distribution of hospitals and schools is little correlated with province-specific characteristics, such as employment/unemployment rates, education attainment rates. In fact, we found no correlation with exception of the size of the public sector, which is a province characteristic related to gender-segregated workplaces. We conclude that the treatment intensity is not significantly associated with province

characteristics, no matter which intensity measurements we use.

Table D.8: Are Treatment Intensity Correlated with the Labor Market Conditions or Education Trends?

|   | Treatment intensity proxy |                     |                     |
|---|---------------------------|---------------------|---------------------|
|   | Measure1                  | Measure2            | Measure3            |
| <b>Dependent Variable</b>                       |                           |                     |                     |
| Unemployment rate                               | 0.0002<br>(0.0003)        | 0.0086<br>(0.0105)  | -0.6419<br>(0.7841) |
| Women's unemployment rate                       | 0.0004<br>(0.0005)        | 0.0126<br>(0.0174)  | -0.9422<br>(1.3002) |
| Men's unemployment rate                         | 0.0002<br>(0.0004)        | 0.0066<br>(0.0125)  | -0.4938<br>(0.9328) |

| Young men's unemployment rate (age 15-30)       | 0.0007<br>(0.0006)        | 0.0208<br>(0.0206)  | -1.5505<br>(1.5347) |
| Proportion of educated young people (age 15-30) | -0.0001<br>(0.0002)       | -0.0028<br>(0.0062) | 0.0062<br>(0.4648)  |
| Proportion of educated young women (age 15-30)  | -0.0004<br>(0.0003)       | -0.0121<br>(0.0084) | 0.9045<br>(0.6262)  |
| Proportion of educated young men (age 15-30)    | 0.0004<br>(0.0003)        | 0.0112<br>(0.0088)  | -0.8370<br>(0.6591) |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth cohort level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified educational institution. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. We also conducted the analysis by excluding observations in 2009, but the results are similar.

### D.3 Less Affected and More Affected Provinces

To examine correlation between treatment intensity and confounding factors, we now compare the results by presenting the observable characteristics of differently affected provinces.

Table D.9 presents the results. For presentation purposes, we divide the sample into two subgroups according to treatment intensity (below median or above median). The less affected province group includes all working-age individuals with treatment intensity below median. The more affected province group includes all working-age individuals with treatment intensity above median. The comparison between the two subgroups shows that the differences are at most 3 percent of the mean value.

Table D.9: Mean, Standard Deviations, and Tests of Covariate Balance at Baseline

|   | Less affected provinces | More affected provinces |
|---|-------------------------|-------------------------|
| <i>Household-level variables</i>                            |                         |                         |
| Number of observations                                      | 624,285                 | 617,968                 |
| % Family with a male head                                   | 99.88                   | 99.91                   |
| Head's years of schooling                                   | 7.36<br>(4.82)          | 7.56<br>(4.73)          |
| Spouse's years of schooling                                 | 6.22<br>(4.80)          | 6.67<br>(4.80)          |
| Family size   | 2.97<br>(1.30)          | 2.99<br>(1.31)          |
| <i>Individual-level variables</i> ( $15 \leq age \leq 64$ ) |                         |                         |
| Number of observations (female)                             | 1,176,349               | 1,161,140               |
| Number of observations (male)                               | 1,119,711               | 1,116,793               |
| Age (female)  | 34.06<br>(13.31)        | 34.35<br>(13.34)        |
| Age (male)  | 33.71<br>(13.38)        | 33.92<br>(13.36)        |
| % Married women   | 64.78                   | 64.92                   |
| % Women have given birth                                    | 56.40                   | 56.25                   |
| % Married men   | 60.56                   | 60.42                   |
| % Men whose wife has had a child                            | 50.81                   | 50.52                   |
| % Women who work for pay                                    | 13.79                   | 14.56                   |
| % In school: girls (age:15-18)                              | 64.33                   | 66.11                   |
| % In school: boys (age:15-18)                               | 70.00                   | 70.10                   |

Less affected provinces (column (1)): all working-age individuals in the provinces with treatment intensity below median. More affected provinces (column (2)): all working-age individuals in the provinces with treatment intensity above median. Standard deviations are presented below each set of statistics.

In fact, we see little correlation between the treatment intensity the characteristics (e.g. unemployment rates, size of the public sector) of the province. We find no correlation with exception of the province characteristic related to gender-segregated workplaces: the size of the public sector. If the public sector is large, then they tend to offer a smaller proportion of job openings for women after the quota. This data pattern makes sense because the proportion of employment in schools and hospitals tends to be smaller for those provinces that have a large public sector size. Other than the size of the public sector, we find no correlation between the treatment intensity and the province characteristics.

We also look how treatment intensity is correlated with the level and growth of college education. To be specific, we look at how treatment intensity is associated with

the proportion of women with college degrees in the pre-treatment period (2008) as well as “changes” in the proportion of women with college degrees in 2008. The unit of observation is each province. The correlation coefficient is 0.24 for the proportion of college-educated women and 0.007 for its change. We also use the women’s average years of schooling as an alternate measurement of education in each province, but again, find no correlation.

## D.4 Testing the Common Trend Assumption

A differences-in-differences approach relies on the assumption that the pretrends among differently affected areas must be comparable, and there should not be any anticipatory effects. Hence, we investigate the pretrends among differently affected areas by conducting placebo tests. To be specific, we allow a placebo treatment in a year different from the actual timing of the quota policy implementation. For example, by using the year 2008 as the fake treatment year, we can check whether people anticipated the effects and whether the trends are comparable. Since this fake treatment precedes the actual date of the policy implementation, the estimator of our interest should be statistically insignificant. Table D.10 shows no effects in the other years, meaning that the policy effects immediately went into effect in 2010; this analysis indicate that there is no evidence of anticipatory effects or post-treatment effects.

Table D.10: Placebo DID Results (Education)

| Dependent Var.        | Attending college |         |         |         |
|-----------------------|-------------------|---------|---------|---------|
| Fake treatment year   | 2007              | 2008    | 2009    | 2011    |
| <b>Panel A: Women</b> |                   |         |         |         |
| Treatment             | -0.006            | -0.007  | 0.008   | 0.004   |
| $\gamma$              | (0.012)           | (0.013) | (0.015) | (0.016) |
| Observations          | 296,063           | 296,063 | 296,063 | 296,063 |
| R-squared             | 0.054             | 0.054   | 0.054   | 0.054   |
| <b>Panel B: Men</b>   |                   |         |         |         |
| Treatment             | -0.016            | -0.017  | -0.013  | -0.007  |
| $\gamma$              | (0.020)           | (0.019) | (0.020) | (0.018) |
| Observations          | 304,105           | 304,105 | 304,105 | 304,105 |
| R-squared             | 0.052             | 0.052   | 0.052   | 0.052   |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the birth cohort level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified educational institution. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. The sample for this analysis is men and women aged 15 to 25 (18 to 35 for graduate school). Each table presents the estimated effects on education enrollment when we use a year other than 2010 as the fake treatment year.

## D.5 How do Education Effects Differ by Treatment Intensity?

The previous results present effects of the quota and find a significant decline in women's four-year college enrollment. Here, we look at heterogenous effects on education. In particular, we report the effects by treatment intensity to show whether reduced job openings monotonically affected the education outcomes.<sup>12</sup> This analysis serves as a robustness check to examine whether the results are consistent with the prediction in that the more treated areas show a stronger impact than the less treated ones.

Table D.11 presents the results for women divided into subgroups according to treatment intensity. We divide women into those in less affected provinces and those in more affected provinces. While we find no significant effects for less affected provinces, we find negative effects for more affected provinces. For more affected provinces, the enrollment rate went down by 9.6 percentage from 65% for any university program (two-year and four-year programs).

Table D.11: DID Results (Education for Women in More/Less Affected Areas)

| Dep. Var.        | Education              |                     |
|------------------|------------------------|---------------------|
|                  | Attended<br>highschool | Attended<br>college |
| Regions          | Less Affected          |                     |
| Post × Intensity | -0.012                 | -0.067**            |
| γ                | (0.031)                | (0.030)             |
| Obs.             | 115,746                | 144,206             |
| R-squared        | 0.054                  | 0.047               |
| Mean control     | 0.658                  | 0.648               |
| Regions          | More Affected          |                     |
| Post × Intensity | -0.062***              | -0.096***           |
| γ                | (0.018)                | (0.012)             |
| Obs.             | 109,744                | 151,857             |
| R-squared        | 0.061                  | 0.030               |
| Mean control     | 0.659                  | 0.632               |

Notes: Heteroskedasticity-consistent standard errors accounting for clustering at the province level in parentheses. The dependent variable is an indicator for whether an individual enrolls in a specified education level. Control variables are year and province fixed effects, rural-urban dummies, birth year, and family background including parent's education. \*Significant at 10% level; \*\*significant at 5% level; \*\*\* significant at 1% level. This table presents estimated coefficients from a linear probability model. The time period is 2006-2015 for the base specification. We also conducted the analysis by excluding observations in 2009, but the results are similar. The sample for this analysis is men and women aged 15 to 25 who are eligible for enrolling in high school and aged 18 to 35 who complete high school and are eligible for enrolling at any university programs.

---

<sup>12</sup>In addition to the results reported above, we look at the effects of the hiring ceiling on wages to see how the quota affected the composition of workers in the labor market. However, we do not find any significant effects. We also look at the effects by household asset to see heterogeneous effects, but do not detect any significant difference by wealth.
